Abstract

We compare the predictions of two distinct dipole models for inclusive and exclusive diffractive processes. While only one of these dipole models contains perturbative saturation dynamics, we show that the predictions of both models are fully consistent with the available HERA data, indicating no compelling evidence for saturation at present HERA energies.

1 Introduction

The color dipole model [1] provides a unified framework for low Bjorken- x Deep Inelastic Scattering (DIS),

$$\gamma^* + p \rightarrow X, \quad (1)$$

diffractive DIS (DDIS),

$$\gamma^* + p \rightarrow p + X, \quad (2)$$

and diffractive exclusive processes, including Deeply Virtual Compton Scattering (DVCS),

$$\gamma^* + p \rightarrow \gamma + p \quad (3)$$

*Talk presented by R. Sandapen at the 26th annual Montreal-Rochester-Syracuse-Toronto (MRST) conference held at Concordia University, Montreal, 12th-14th May 2004.

where the final state photon is real, and vector meson production

$$\gamma^* + p \rightarrow v + p \quad (4)$$

where v is a vector meson (ρ , ϕ , J/Ψ , etc.). In reactions (1) and (2), X represents an inclusive sum over hadronic states.

In this framework, the DIS cross-section, hence the total structure function $F_2(x, Q^2)$, factorizes into the photon light-cone wavefunction $\Psi_\gamma(r, z; Q^2)$ and a dipole cross-section $\sigma_d(r, s)$:

$$\sigma_{\gamma^* p \rightarrow X} = \int d^2\mathbf{r} dz |\Psi_\gamma(r, z; Q^2)|^2 \sigma_d(r, s) . \quad (5)$$

Here, r is the transverse size of the color dipole, z is the fraction of the photon's light-cone momentum carried by the quark and s is the photon-proton center-of-mass energy.

For diffractive processes, the factorization occurs at the amplitude level. For instance, in DVCS, the forward differential cross-section is given as

$$\left. \frac{d\sigma}{dt} \right|_{t=0} = \frac{1}{16\pi} \left[\int d^2\mathbf{r} dz \Psi_\gamma^*(r, z; Q^2) \sigma_d(r, s) \Psi_\gamma(r, z; 0) \right]^2 . \quad (6)$$

Similarly in vector meson production, the wavefunction for the real photon is replaced by the meson light-cone wavefunction: $\Psi_\gamma(r, z; 0) \rightarrow \Psi_v(r, z; M_v^2)$. For DDIS, we use completeness over a sum of all possible final states to write:

$$\left. \frac{d\sigma}{dt} \right|_{t=0} = \frac{1}{16\pi} \left[\int d^2\mathbf{r} dz |\Psi_\gamma(r, z; Q^2)|^2 \sigma_d^2(r, s) \right]^2 . \quad (7)$$

We assume an exponential ansatz for the t dependence,

$$\frac{d\sigma}{dt} = \left. \frac{d\sigma}{dt} \right|_{t=0} \exp(-B|t|) \quad (8)$$

where the coefficient B is called the diffractive slope and is obtained from experiment. Small corrections for the real parts of the amplitudes, neglected in the above formulae, are also included.

It is noteworthy that (5,6,7) hold beyond the validity of perturbation theory: the dipole framework incorporates both hard and soft physics associated with small and large dipole size r respectively. The universal dipole cross-section, σ_d contains all the physics of diffraction: gluon ladders of QCD, pomeron exchange of Regge theory, etc. In particular, at high enough energies, it should also contain the physics of saturation, that is saturation in the energy variable, at fixed Q^2 . The important phenomenological question of interest here, is whether such saturation effects can be seen in the data at present HERA energies.

2 Low x perturbative saturation

Perturbative QCD evolution in the low x regime is described by the Balitsky-Fadin-Kuraev-Lipatov (BFKL) equation. The latter predicts a fast rise of the total cross-section with increasing energy at fixed Q^2 . This rise has to be tamed in order not to violate unitarity. Put another way, the occupation number of gluons in the proton cannot become arbitrarily large. At high enough energy, gluon recombination should start to compete with gluon splitting and tame the rise of cross-sections. This is the saturation regime: a new high density and weakly coupled limit of QCD. In this regime, an effective field theory, the color glass condensate [2] describes the quantum evolution of soft gluons in a classical background color field. In the limit of a dilute background, one regains the BFKL equation [2].

The recent dipole model of Iancu et al. [3] is anticipated to capture the essential dynamics of the color glass condensate, incorporating saturation and BFKL dynamics in appropriate limits. In the next Section, we will discuss this model, together with another dipole model, proposed by Forshaw et al. [4], which is based on Regge theory and does not contain low x saturation. We shall start with the latter.

3 Two dipole models

Some years ago, Forshaw, Kerley and Shaw (FKS) proposed the following ansatz for the dipole cross-section :

$$\hat{\sigma}(s, r) = \hat{\sigma}_{\text{soft}}(s, r) + \hat{\sigma}_{\text{hard}}(s, r), \quad (9)$$

in which each term has a Regge type energy dependence on the dimensionless energy variable $r^2 s$:

$$\hat{\sigma}_{\text{soft}}(s, r) = a_0^S \left(1 - \frac{1}{1 + a_4^S r^4} \right) (r^2 s)^{\lambda_S}, \quad (10)$$

$$\hat{\sigma}_{\text{hard}}(s, r) = (a_2^H r^2 + a_6^H r^6) \exp(-\nu_H r) (r^2 s)^{\lambda_H}. \quad (11)$$

This form is reminiscent of the idea of two pomeron exchange of Donnachie and Landshoff [5]. The coefficients in the polynomials in r , as well as ν_H and $\lambda_{S,H}$, are free parameters fitted to F_2 and real photoabsorption data. The fitted values of $\lambda_{S,H}$ are indeed consistent with the hard and soft pomeron intercepts respectively. In addition, to allow for possible confinement effects in the photon wavefunction at large r , the latter was multiplied by an adjustable Gaussian enhancement factor,

$$f(r) = \sqrt{\frac{1 + B \exp(-c^2(r - R)^2)}{1 + B \exp(-c^2 R^2)}}. \quad (12)$$

This model does not contain any perturbative low x saturation. Consequently, at high enough energies, the power-like energy growth of (especially) the hard term will make the cross-section for small dipoles exceed that for large dipoles. As can be

seen in Figure 1, this starts to happen only at the top of the HERA range indicating that the structure function data are not at high enough energy to require saturation corrections to be built in [6]. The (energy dependent) flattening of the cross-section at large r reflects low Q^2 (fixed s) saturation. This is of non-perturbative origin and should not be confused with low x (fixed Q^2 , larger than Λ_{QCD}^2) perturbative saturation.

The CGC dipole model describes both BFKL and saturation dynamics. Specifically, the following functional form is adopted:

$$\begin{aligned}\hat{\sigma} &= 2\pi R^2 \mathcal{N}_0 \left(\frac{rQ_s}{2} \right)^{2\left[\gamma_s + \frac{\ln(2/rQ_s)}{\kappa\lambda \ln(1/x)}\right]} & \text{for } rQ_s \leq 2 \\ &= 2\pi R^2 \{1 - \exp[-a \ln^2(brQ_s)]\} & \text{for } rQ_s > 2,\end{aligned}\quad (13)$$

where the saturation scale $Q_s \equiv (x_0/x)^{\lambda/2}$ GeV. Hence, the first line is the BFKL term and the second term is the saturation term. The CGC dipole cross-section saturates as $x \rightarrow 0$, including both perturbative and non-perturbative saturation. γ_s and κ are fixed by the leading order BFKL equation with saturation boundary conditions [3]. The coefficients a and b are uniquely determined by ensuring continuity of the cross-section and its first derivative at $rQ_s = 2$. The coefficient $\mathcal{N}_0$ is strongly correlated to the definition of the saturation scale and the authors find that the quality of fit to F_2 data is only weakly dependent upon its value. For a fixed value of $\mathcal{N}_0$, there are therefore three parameters which need to be fixed by a fit to the data, i.e. x_0 , λ and R . The CGC model does not use any enhancement factor to modify the photon wave function at large r . Nevertheless, a similar effect is achieved by the use of lighter quark masses[†].

The FKS and CGC dipole cross-sections are compared in Figure 1.

Figure 1: *Left:* The two pomerons (FKS) dipole model at different energies. *Right:* The CGC dipole model at different x .

[†]Figure 3 of Ref. [8] illustrates this statement.

4 Selected results for diffractive processes

We now compare predictions of the two dipole models for the energy dependence of the total cross-section for various diffractive processes. We refer the reader to the original papers [7, 8, 9] for detailed discussions of these calculations and for the references for the data from the H1 and ZEUS Collaborations.

4.1 Diffractive Deep Inelastic Scattering

Analogous to the structure function $F_2(x, Q^2)$, one can define a diffractive structure function $F_2^{D(4)}(\beta = x_P/x, x_P, Q^2, t)$, where x_P can be thought as the momentum fraction of the proton carried by the pomeron. Integrating over t , one obtains the quantity referred to as $F_2^{D(3)}$. A necessary complication arises here: for large diffractive mass M_X , an additional contribution due to the $q\bar{q}g$ component of the photon wavefunction becomes important. This introduces the strong coupling α_s which defines the normalization of the $q\bar{q}g$ component. We are free to adjust the value of α_s as well as that of the forward slope for inclusive diffraction, B , within the range acceptable to experiment, in order to achieve best agreement with data for each of the dipole models. As can be seen in Figure 2, while the stronger energy dependence of the FKS model manifests itself in a steeper rise as x_P decreases, both models agree rather well with the data from H1 [7].

Figure 2: DDIS [7]. Dashed: FKS (no saturation). Solid: CGC (saturation).

4.2 Deeply Virtual Compton Scattering

To compute the DVCS cross-section within the dipole model, we evaluate the light-cone wavefunction of the outgoing real photon at $Q^2 = 0$. This means that the contribution due to longitudinally polarised photons vanishes and the process is purely transverse. Here we provide the first predictions of the CGC model for DVCS. The FKS predictions were given and discussed in Ref. [8]. The comparison to H1 data and more recent ZEUS data is shown in Figure 3. Note that we use a lower value for the B slope when comparing to ZEUS data.

Figure 3: DVCS. Dashed: FKS (no saturation). Solid: CGC (saturation).

As can clearly be seen, beyond the HERA range, the energy dependence of the FKS prediction becomes much steeper than that of the CGC prediction. Both models describe the available data.

4.3 Light vector meson production

To compute the cross-section for vector meson production in the dipole approach, one needs the vector meson light-cone wavefunction. The latter is usually modeled upon that of the photon. The spinorial part of the meson wavefunction is assumed to be the same as in the photon case (i.e with the γ^μ vertex) while the scalar part can be taken to be the boosted solution of the Schrödinger equation with a harmonic oscillator potential[‡]. The resulting wavefunction is referred to as a boosted Gaussian. The free parameters of the wavefunction are fixed using the normalization and leptonic decay width constraints [9]. Here, we show only predictions for the energy dependence of

[‡]Actually the original parameterization (see Ref. 10 of Ref. [9]) includes a Coulombic correction to the harmonic oscillator potential. However, as explained in Ref. [9], the resulting light-cone wavefunction has a spurious singularity which affects the fixing of free parameters.

the total cross-section for ρ production, using the boosted Gaussian wavefunction, together with a B slope dependent on Q^2 and the mass of the vector meson M_ρ . Predictions using other parameterizations of the meson wavefunction and for the ϕ [§] can be found in Ref. [9]. As can be seen from Figure 4, the two dipole models agree with each other and the available data. As expected, this agreement rapidly breaks down as we go beyond the HERA energy range.

Figure 4: ρ production [9]. Dashed: FKS (no saturation). Solid: CGC (saturation).

5 Conclusion

We have shown that the predictions of the two pomerons (FKS) dipole model and the recent color glass condensate (CGC) dipole model are fully consistent with the HERA data on inclusive and exclusive diffractive processes. We also provided new predictions of the CGC model for the DVCS process. We conclude that the present data show no clear signs for saturation dynamics. Future precise data from HERA may help to discriminate between the two different theoretical approaches.

Acknowledgements

This research was supported in part by the UK Particle Physics and Astronomy Research Council. R.S thanks the organisers of MRST 04 for a very enjoyable conference and the theoretical physics group of Laval University for financial support.

[§]The data on the energy dependence of the cross-section for ϕ production is too imprecise to be useful.
